Abstract

In this paper, we investigate the optimization of mutual proportional reinsurance — a mutual reserve system that is intended for the collective reinsurance needs of homogeneous mutual members, such as P&I Clubs in marine mutual insurance and reserve banks in the U.S. Federal Reserve. Compared to general (non-mutual) insurance models, which involve one-sided impulse control (i.e., either downside or upside impulse) of the underlying insurance reserve process that is required to be positive, a mutual insurance differs in allowing two-sided impulse control (i.e., both downside and upside impulse), coupled with the classical proportional control of reinsurance. We prove that a special band-type impulse control (a, A, B, b) with $a = 0$ and $a < A < B < b$, coupled with a proportional reinsurance policy (classical control), is optimal when the objective is to minimize the total maintenance cost. That is, when the reserve position reaches a lower boundary of $a = 0$, the reserve should immediately be raised to level A; when the reserve reaches an upper boundary of b, it should immediately be reduced to a level B.

†This work was supported by the Norwegian Research Council: Forskerprosjekt ES445026, "Stochastic Dynamics of Financial Markets."

An interesting finding produced by the study reported in this paper is that there exists a situation such that if the upside fixed cost is relatively large in comparison to a finite threshold, then the optimal band control is reduced to a downside only (i.e., dividend payment only) control in the form of $(0, 0; B, b)$ with $a = A = 0$. In this case, it is optimal for the mutual insurance firm to go bankrupt as soon as its reserve level reaches zero, rather than to jump restart by calling for additional contingent funds. This finding partially explains why many mutual insurance companies, that were once quite popular in the financial markets, are either disappeared or converted to non-mutual ones.

1 Introduction

Reinsurance has been long investigated as an intrinsic part of commercial insurance, of which the mainstream modeling framework is profit maximization with the one-sided impulse control of an underlying reserve process. There are two types of one-sided impulse control: downside-only impulse control (such as a dividend payment) with a fixed cost K^-(e.g., Cadenillas *et al.* [8], Hojgaard and Taksar [15]) and upside-only impulse control (such as inventory ordering) with a fixed cost K^+ (e.g., Bensoussan *et al.* [2], Eisenberg and Schmidli [13], Sulem [19]). In this paper, we examine mutual proportional reinsurance — a mutual reserve system that is intended for the collective reinsurance needs of homogeneous mutual members, such as the P&I Clubs in marine mutual insurance (e.g., Yuan [20]) and the reserve banks in the U.S. Federal Reserve (e.g., Dawande *et al.* [11]). A mutual insurance differs from a general (non-mutual) insurance in two key dimensions: 1) a mutual system is not for profit and 2) a mutual reserve involves two-sided impulse control (i.e., both a dividend refund as a downside impulse to decrease the reserve with cost K^- and a call for funds as an upside impulse to increase the reserve with cost K^+). It should be noted that the reserve process for a general insurance must always be positive (above zero), and the insurance firm is considered bankrupt as soon as its reserve falls to zero.

The mutual proportional reinsurance model developed in this paper is a generalization of the proportional reinsurance models (e.g., Cadenillas *et al.* [8], Hojgaard and Taksar [15], Eisenberg and Schmidli [13]) and is modified with the two differing characteristics noted above. More specifically, the proportional reinsurance rate can be adjusted in continuous time, and the underlying mutual reserve process is regulated by a two-sided impulse control in terms of a contingent dividend payment (i.e., a downside impulse control to decrease the mutual reserve level) and contingent call for contributions (i.e., an upside impulse control to increase the mutual reserve level). The corresponding mathematical problem for mu-

tual proportional reinsurance becomes a two-sided impulse control system combined with a classical rate control in continuous time, a problem yet to be posed in insurance research. A problem that involves a mix of impulse control and classical control is termed a hybrid control problem in control theory, of which the diculty has been well noted (e.g., Bensoussan and Menaldi [3], Branicky and Mitter [5], Abate *et al.* [1]).

A pure two-sided impulse control problem (i.e., without a classical rate control) was investigated by Constantinides [9] in the form of cash management. Constantinides and Richard [10] showed an optimal two-sided impulse control policy to exist in the form of a band control, denoted with four parameters as $(a, A; B, b)$ with $a < A \leq B < b$. In other words, when the reserve position reaches a lower boundary a, then the reserve should immediately be raised to level A; when the reserve reaches upper boundary b, it should immediately be reduced to level B. For our mutual proportional reinsurance problem, we specify the corresponding Hamilton-Jacobi-Bellman (HJB) equation and the associated quasi-variational inequalities (QVI), from which we analytically solve the optimal value function. We then prove that a special band-type impulse control $(0, A, B, b)$ with $a = 0$, combined with a proportional reinsurance policy (classical control), is optimal when the objective is to minimize the total maintenance cost. An interesting finding reported here is that there exists a situation such that if the upside fixed cost K^+ is relatively large in comparison to a finite threshold $\overline{K^+}$, then the optimal band control is reduced to a downside only (i.e., a dividend payment only) control in the form of $(0, 0; B, b)$ with $a = A = 0$. In this case, it is optimal for the mutual insurance to go bankrupt as soon as its reserve level falls to zero, rather than to restart by calling for additional contingent funds. This finding partially explains why many mutual insurance companies, that were once quite popular in the financial markets, are either disappeared or converted to non-mutual ones.

The remainder of the paper is organized as follows. In Section 2, we formulate the mathematical model and specify the HJB equation and the QVI of the corresponding stochastic control problem. We solve the QVI for the optimal value function in Section 3. In Section 3.2, we characterize and analyze the threshold $\overline{K^+}$. In Section 4, we prove the verification theorem and verify the optimal control. Finally, we make concluding remarks in Section 5.

2 The Model

2.1 Feasible Control

The classical Cramer-Lundberg model of an insurance reserve (surplus) is described via a compound Poisson process:

$$D(t) = D(0) + pt - \sum_{i=0}^{N(t)} Y_i,$$

where $D(t)$ is the amount of the surplus available at time t, quantity p represents the premium rate, $N(t)$ is the Poisson process of incoming claims and Y_i is the size of the ith claim. This surplus process can be approximated by a diffusion process with drift $\mu = p - \lambda E[Y]$ and diffusion coefficient $\sigma = \sqrt{\lambda EY^2}$, where λ is the intensity of the Poisson process $N(t)$. We assume that the insurer always sets $p > \lambda E[Y]$ (i.e. $\mu > 0$). Thus, with no control, the reserve process $X(t)$ is described by

$$X(t) = X(0) + \int_0^t \mu ds + \int_0^t \sigma dW_s, \tag{2.1}$$

where W_t is a standard Brownian motion.

We start with a probability space $(\Omega, \mathcal{F}, P)$, that is endowed with *information filtration* $\mathcal{F}_t$ and a standard Brownian motion W_t on Ω adapted to $\mathcal{F}_t$. Two types of controls are used in this model. The first is related to the ability to directly control its reserve by raising cash from or making refunds to members at any particular time. The second is related to the mutual insurance firm's ability to delegate all or part of its risk to a reinsurance company, simultaneously reducing the incoming premium (all or part of which is in this case channeled to the reinsurance company). In this model, we consider a *proportional reinsurance* scheme. This type of scheme corresponds to the original insurer paying u fraction of the original claim. The premium rate coming to the original insurer is simultaneously reduced by the same fraction. The reinsurance rate can can be chosen dynamically depending on the situation.

Mathematically, control U takes a triple form:

$$U = \{u(t), (\tau_1, \tau_2, ...), (\xi_1, \xi_2...)\}, \tag{2.2}$$

where $0 \leq u(t) \leq 1$ is a predictable process with respect to $\mathcal{F}_t$, the random variables $\tau_1 < \tau_2 < ...$ constitute an increasing sequence of stopping times with respect to $\mathcal{F}_t$, and ξ_i is a sequence of $\mathcal{F}_{\tau_i}$-measurable random variables, $i = 1, 2, ...$

The meaning of these controls is as follows. The quantity $u(t)$ represents the fraction of the claim that the mutual insurance scheme pays if the claim arrives at time t. Suppose that $u(t) = u$ is chosen at time t. Then, in the diffusion approximation (2.1), drift μ and diffusion coefficient σ are reduced by factor u (see Cadenillas *et at.* [7], Hojgaard and Taksar [15]).

The fact that the process $u(t)$ is adapted to information filtration means that any decision has to be made on the basis of past rather than the future information. The stopping times τ_i represent the times when the ith intervention to change the reserve level is made. If $\xi_i > 0$, then the decision is to raise cash by calling the members/clients. If $\xi_i < 0$, then the decision is to make a refund. The fact that τ_i is a stopping time and ξ_i is $\mathcal{F}_{\tau_i}$-measurable also indicates that the decisions concerning when to make a contingent call and how much cash to raise are made on the basis of only past information. The same applies to the refund decisions.

Once control U is chosen, the dynamics of the reserve process becomes:

$$X(t) = X(0) + \int_0^t u(s)\mu ds + \int_0^t u(s)\sigma dW_s + \sum_{\tau_i \le t} \xi_i. \tag{2.3}$$

Define the ruin time as

$$\tau = \inf\{t : X(t) < 0\}. \tag{2.4}$$

Control U is called admissible for initial position x if, for $X(0) = x$ for any $\tau_i \le \tau$,

$$X(\tau_i) \ge 0; \tag{2.5}$$

and if

$$E \sum_{\tau_i \le \tau} e^{-r\tau_i} |\xi_i| (K^- \mathbb{1}_{\xi_i < 0} + K^+ \mathbb{1}_{\xi_i > 0}) < \infty. \tag{2.6}$$

We denote the set of all admissible controls by $\mathcal{U}$.

The meaning of admissibility is as follows. At any time the decision to make a refund is made, the refund amount cannot exceed the available reserve. As can be seen in the following, if this condition is not satisfied, then one can always achieve a cost equal to $-\infty$, simply by making an infinitely large refund. The second condition of admissibility is a rather natural technical condition of integrability.

2.2 Cost Structure and Value Function

The objective in this model is to minimize the operational cost and the lost opportunity to invest the money in the market. Cost function g is defined as

$$g(\xi) = K^+ \mathbb{1}_{\xi>0} + c^+\xi^+ + K^- \mathbb{1}_{\xi<0} - c^-\xi^-. \tag{2.7}$$

Here, ξ^+ and ξ^- denote the positive and negative components of ξ, that is, $\xi^+ = \max(\xi, 0)$ and $\xi^- = -\min(\xi, 0)$. The costs associated with refunds are of a different nature. A contingent call always increases the total cost, whereas a refund decreases it. However fixed set-up costs $K^+ > 0$ and $K^- > 0$ are incurred regardless of of the size of a contingent call or a refund. In addition, when the call is made and the cash is raised, there is a proportional cost associated with the amount raised. The constant $c^+ > 1$ represents the amount of cash that needs to be raised in order for one dollar to be added to the reserve. If the reserve is used for a refund, then a part of it may be charged as tax. The constant $0 < c^- < 1$ represents the amount actually received by the shareholders for each dollar taken from the reserve.

Given a discount rate r, the cost functional associated with the control U is defined as

$$C(x; U) = E_x \left\{ \sum_{i=1}^{\infty} g(\xi_i)\, e^{-r\tau_i} \mathbb{1}_{\tau_i \le \tau} \right\}. \tag{2.8}$$

The objective is to find the value function,

$$V(x) = \inf_{U \in \mathcal{U}} C(x; U), \tag{2.9}$$

and *optimal control* U^*, such that

$$C(x, U^*) = V(x).$$

2.3 Variational Inequalities for the Optimal Value Function

For each $0 \le u \le 1$, define the infinitesimal generator $\mathcal{L}^u$. For any twice continuously differentiable function $\phi : [0, \infty) \mapsto \mathbb{R}$

$$(\mathcal{L}^u \phi)(x) = \frac{1}{2} u^2 \sigma^2 \frac{d^2\phi(x)}{dx^2} + u\mu \frac{d\phi(x)}{dx}. \tag{2.10}$$

Let M be the *inf-convolution operator*, defined as

$$\mathcal{M}\phi(x) = \inf_{\xi \neq 0} \left[g(\xi) + \phi(x + \xi) \right]. \tag{2.11}$$

Definition 2.1. *The QVI of the control problem are*

$$\mathcal{L}^u V - rV \geq 0, \tag{2.12}$$

and

$$\mathcal{M}V \geq V, \tag{2.13}$$

together with the tightness condition

$$(\mathcal{M}V - V) \left(\min_{u \in [0,1]} (\mathcal{L}^u V - rV) \right) = 0. \tag{2.14}$$

3 Solution of the QVI

3.1 The HJB Equation in the Continuation Region

In this model, the application of the control that is related to calls and refunds results in a jump in the reserve process. This type of model is considered in the framework of the so-called*impulse control*. Because we also have a control whose application changes the drift and the diffusion coefficient of the controlled process, the resulting mathematical problem becomes a mixed regular-impulse control problem (e.g., Cadenillas *et al.* [7]). In the case of a pure impulse control, the optimal policy is of the (a, A, B, b) type, where the four parameters used to construct the optimal control must be computed as a part of a solution to the problem (see Cadenillas and Zapatero [6], Constantinides and Richard [10], Harrison and Taylor [14], and Paulsen [17]). Parameters a and b represent the levels at which the intervention (application of impulses) must be made, whereas A and B stand for the positions that the controlled process must be in after the intervention is made. This is a so-called *band-type* policy, with (a, A) and (B, b) understood as the two bands that determine the nature of the optimal control. The interval $[a, b]$ is called the *continuation region*. When the process falls inside the continuation region, no interventions/impulses are applied. When an intervention is initiated, the time when the process reaches one of the boundaries of the continuation region corresponds to one of τ_i.

We conjecture that, in our case, the optimal intervention (impulse control) component of the problem is also of the band type. Moreover, as the following analysis implicitly shows,

we can narrow our search for the optimal policy to a special band-type control $(0, A, B, b)$, where the level a associated with the contingent calls is set to zero. Therefore, only three of the four band-type policy parameters remain unknown. After finding these parameters (and determining the optimal drift/diffusion control in the continuation region), we will see that the cost function associated with this policy satisfies the QVI.

The derivation of the value function is similar to [8] and [7] . Suppose that $V(x)$ satisfies all of the QVI conditions: (2.12), (2.13) and (2.14). First note that the function $V(x)$ is a decreasing function of x, and thus $V' \leq 0$. To satisfy (2.14), for any $x \geq 0$, at least one of the two functions on the left side of the equation should be equal to zero. We conjecture that the value function has the following structure.

$$V - \mathcal{M}V = 0 \tag{3.15}$$

for $x \in 0 \cup [b, +\infty)$. Also

$$\min_{u \in [0,1]} (\mathcal{L}^u V - rV) = 0 \tag{3.16}$$

for $x \in (0, b)$.

Assume that $u^* \in [0, 1]$ minimizes the function $\mathcal{L}^u V - rV$ in foregoing equation. If $V'' > 0$ then

$$u^* = -\frac{\mu V'}{\sigma^2 V''}, \tag{3.17}$$

provided that the right-hand side of (3.17) belongs to $(0, 1)$. (Note that if $V''(x) = 0$, then (3.16) cannot be satisfied and we exclude $V''(x) = 0$ from consideration.)

Substituting (3.17) into (3.16), we get

$$2r\sigma^2 V_1 V_1'' + \mu^2 (V_1')^2 = 0. \tag{3.18}$$

The general solution for (3.18) is

$$V_1(x) = -C_1 (x + C_2)^\gamma, \tag{3.19}$$

where C_1 and C_2 are free constants to be determined later, and

$$\gamma = \frac{1}{1 + \frac{\mu^2}{2r\sigma^2}}. \tag{3.20}$$

It is easy to see that $0 < \gamma < 1$. From (3.17), we obtain the expression for $u^*(x)$ (provided that $C_1 > 0$, which will be verified later):

$$u^*(x) = \frac{\mu (x + C_2)}{\sigma^2 (1 - \gamma)}. \tag{3.21}$$

Note that the solution of (3.18) coincides with the solution of (3.16) only in the region where

$$0 < \frac{\mu}{\sigma^2 (1-\gamma)} (x + C_2) < 1.$$

From this expression, we conjecture that there is a switching point x_0 such that $u(x) = 1$ when $x > x_0$. As $u^*(x_0) = 1$, by virtue of the equation (3.21), we obtain the following expression for x_0:

$$x_0 = \frac{\sigma^2 (1-\gamma)}{\mu} - C_2. \tag{3.22}$$

For $x > x_0$, $u^*(x) = 1$; and the corresponding differential equation becomes

$$\frac{1}{2}\sigma^2 V_2'' + \mu V_2' - r V_2 = 0. \tag{3.23}$$

The general solution for (3.23) is

$$V_2(x) = C_3 e^{\rho_1 (x - x_0)} + C_4 e^{-\rho_2 (x - x_0)}, \tag{3.24}$$

where

$$\rho_1 = \frac{\sqrt{\mu^2 + 2r\sigma^2} - \mu}{\sigma^2} \tag{3.25}$$

$$\rho_2 = \frac{\sqrt{\mu^2 + 2r\sigma^2} + \mu}{\sigma^2}, \tag{3.26}$$

with $0 < \rho_1 < \rho_2$. Standard arguments show that

$$V'(x) = -c^- \tag{3.27}$$

for $x \geq b$ (see e.g., Cadenillas *et al.* [7]). The boundary conditions for the equation are rather tricky. If 0 and b are the points at which the impulse control (intervention) is initiated then the boundary conditions at these points become

$$V(0) = V(A) + K^+ + c^+ A \tag{3.28}$$

$$V'(A) = -c^+ \tag{3.29}$$

$$V(b) = V(B) + K^- - c^-(b - B) \tag{3.30}$$

$$V'(B) = -c^-. \tag{3.31}$$

However, if bankruptcy is allowed and no intervention is initiated when the process reaches 0, then the boundary condition at 0 becomes straightforward: $V(0) = 0$ (see Cadenillas and Zapatero [8] and Cadenillas, *et al.* [7]). In our case, whether 0 is the point that corresponds

to the intervention in the form of a contingent call or whether it corresponds to bankruptcy is not given a priori; rather it is part of the solution to the problem.

We seek the solution by finding a function V such that

$$V(x) = V_1(x), 0 \leq x \leq x_0, \tag{3.32}$$
$$V(x) = V_2(x), x \geq x_0 \leq b, \text{ and} \tag{3.33}$$
$$V(x) = V(b) - c^-(x - b), x \geq b. \tag{3.34}$$

To find the free constants in the expressions for V_1 an V_2 and to paste different pieces of the solution together we apply the *principle of smooth fit* by making the value and the first derivatives to be continuous at the switching points x_0 and b,

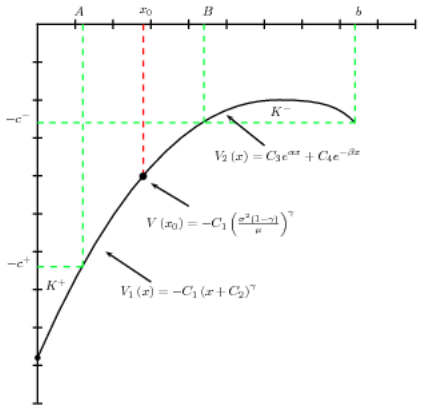

$$V_1(x_0) = V_2(x_0), \tag{3.35}$$
$$V_1'(x_0) = V_2(x_0)', \tag{3.36}$$
$$V_2'(b) = -c^-, \tag{3.37}$$

where x_0 is defined by (3.22).

(It should be noted that the function V, which is constructed from (3.32)-(3.34) subject to conditions (3.28)-(3.31) and (3.35)-(3.37), corresponds to the case in which the optimal policy leads to $\tau = \infty$.) We begin by constructing such a function. The main technique is not to consider the function V itself, but rather first to construct V'.

The form of $V'(x)$ is shown in Figure 1.

Figure 1: Optimal Policy Parameters

From $u^*(x_0) = 1$ and (3.17), we have $V_1''(x_0) = -\frac{\mu}{\sigma^2} V_1'(x_0)$. By the continuity on V and V' at x_0, and by (3.23), we have $\frac{\mu}{2r} V_2'(x_0) = V_2(x_0)$. From this relation and (3.24), we have

$$C_4 = \frac{\rho_1 \frac{\mu}{2r} - 1}{\rho_2 \frac{\mu}{2r} + 1} C_3.$$

Let $\beta = \frac{\rho_1 \cdot \frac{\mu}{2r} - 1}{\rho_2 \cdot \frac{\mu}{2r} + 1}$. Then, $C_4 = \beta C_3$, and we can write

$$V_2(x; C_3) = C_3 e^{\rho_1 (x - x_0)} + \beta C_3 e^{-\rho_2 (x - x_0)}.$$

We can easily get the inequalities:

$$-1 < \beta < 0. \tag{3.38}$$

From (3.22), we get

$$V_1(x_0) = -C_1 (x_0 + C_2)^\gamma = -C_1 \left(\frac{\sigma^2 (1 - \gamma)}{\mu} \right)^\gamma.$$

From $V_2(x_0) = C_3 + \beta C_3$, and from the continuity of V at x_0, we obtain the expression for C_1:

$$C_1 = -(1 + \beta) \left(\frac{\sigma^2 (1 - \gamma)}{\mu} \right)^{-\gamma} C_3.$$

Let $\lambda = -(1 + \beta) \left(\frac{\sigma^2 (1 - \gamma)}{\mu} \right)^{-\gamma}$. (Obviously, $\lambda < 0$ since $\beta > -1$.) Now, we can write V_1 in terms of C_2 and C_3:

$$V_1(x; C_2, C_3) = -\lambda C_3 (x + C_2)^\gamma.$$

What remains is to determine C_2 and C_3. Once these constants are found, we have $V_1(x)$ and $V_2(x)$, and thus $V(x)$. Let

$$V(x, C_2, C_3) = \begin{cases} V_1(x; C_2, C_3) = -\lambda C_3 (x + C_2)^\gamma & , \text{for } 0 < x \leq x_0 \\ V_2(x; C_3) = C_3 e^{\rho_1 (x - x_0)} + \beta C_3 e^{-\rho_2 (x - x_0)} & , \text{for } x \geq x_0 \end{cases}$$

where $x_0 = \frac{\sigma^2 (1 - \gamma)}{\mu} - C_2$.

Note that if $C_2 \geq 0$ and $C_3 < 0$, then it is easy to show that for $x > 0$, $V_1'(x; C_2, C_3) < 0$, $V_1'''(x; C_2, C_3) < 0$ and $V_2'(x; C_2, C_3) < 0$, $V_2'''(x; C_2, C_3) < 0$. Therefore, $V(x, C_2, C_3)$ is decreasing on $x > 0$ and$V'(x, C_2, C_3)$ is concave on $x > 0$. In the remainder of this section,

we find C_2 and C_3 and complete the construction of the function V. We do this in an implicit manner by adopting an auxiliary problem in which no contingent calls are allowed and by using the optimal value function of that problem to‘ construct the function V.

Let's consider a slightly different problem in which only those controls U for which ξ_i on the right-hand side of (2.2) are negative allowed. This problem is similar to that considered in Cadenillas *et al.* [7]. Let $v(x)$ be the optimal value function for this problem. As was shown in [7], the function v satisfies the same HJB equation, except for boundary conditions (3.28) and (3.29). These conditions are replaced by $v(0) = 0$.

The same arguments as those above show that we can make the conjecture that the function v should be sought as a solution to (3.39)-(3.44) below.

$$2r\sigma^2 v(x) v''(x) + \mu^2 (v'(x))^2 = 0 \text{ for } 0 \leq x \leq \tilde{x}_0 \tag{3.39}$$

$$\frac{1}{2}\sigma^2 v''(x) + \mu v'(x) - rv(x) = 0 \text{ for } \tilde{x}_0 < x \leq \tilde{b} \tag{3.40}$$

$$v(0) = 0 \tag{3.41}$$

$$v'\left(\tilde{b}\right) = -c^- \tag{3.42}$$

$$v'\left(\tilde{B}\right) = -c^- \tag{3.43}$$

$$v\left(\tilde{b}\right) = v\left(\tilde{B}\right) + K^- - c^-\left(\tilde{b} - \tilde{B}\right), \tag{3.44}$$

where $\tilde{x}_0 = \frac{\sigma^2(1-\gamma)}{\mu}$.

3.1.1 A solution to the auxiliary problem

First note that a general solution to (3.39), (3.41) is $-cx^\gamma$, where γ is the same as in (3.20) and c is a free constant, and a general solution to (3.40) is $-a_1 e^{\rho_1(x-\tilde{x}_0)} - a_2 e^{\rho_2(x-\tilde{x}_0)}$, where ρ_1 and ρ_2 are the same as in (3.25),(3.26).

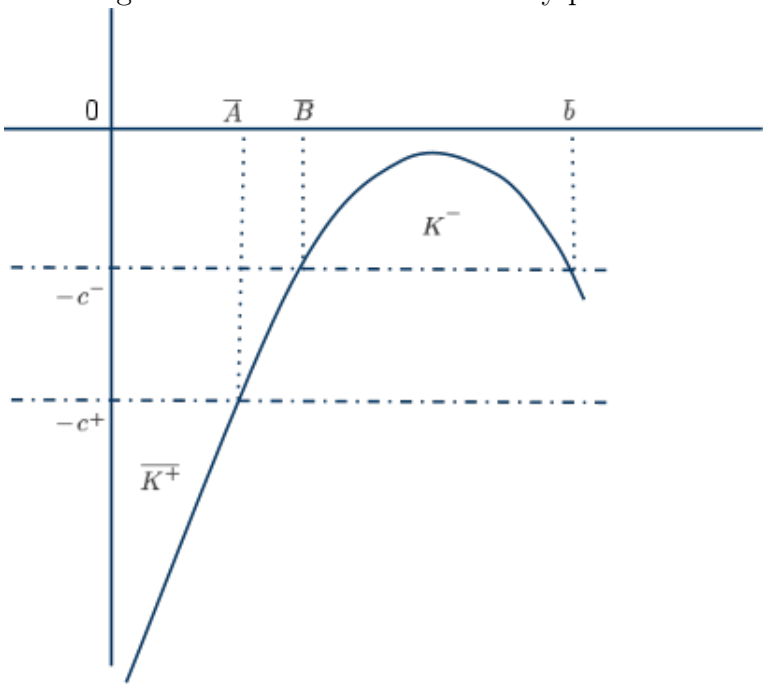

To solve our auxiliary problem we apply the same technique as that used in Cadenillas *et al.* [7]. We begin with $H(x)$, which is defined as follows.

$$H(x) = \begin{cases} -\gamma x^{\gamma-1}, & 0 < x \leq \tilde{x}_0 \\ -a_1\rho_1 e^{\rho_1(x-\tilde{x}_0)} + a_2\rho_2 e^{-\rho_2(x-\tilde{x}_0)}, & x \geq \tilde{x}_0. \end{cases} \tag{3.45}$$

In this expression, constants a_1 and a_2 are chosen in such a way that $-a_1\rho_1 + a_2\rho_2 = -\gamma\tilde{x}_0^{\gamma-1}$ and $-a_1\rho_1^2 + a_2\rho_2^2 = -\gamma(\gamma-1)\tilde{x}_0^{\gamma-2}$. That is, the functions H and H' are continuous at $\tilde{x}_0$.

(Note that $H(x)$ is a derivative of $-x^{\gamma}$ on $[0, \tilde{x}_0]$ and $H(x)$ is a derivative of $-a_1 e^{\rho_1(x-\tilde{x}_0)} - a_2 e^{\rho_2(x-\tilde{x}_0)}$ on $[\tilde{x}_0, \infty)$.) We next examine the family of functions $MH(x)$, where $M > 0$. We seek M^* such that $M^*H(x)$ becomes the derivative of the optimal value function v.

Figure 2: Solution to the auxiliary problem

To this end, we start by finding points $\tilde{b}_M$ and $\tilde{B}_M$ such that $\tilde{b}_M = \max\{x : MH(x) = -c^-\}$ and $\tilde{B}_M = \min\{x : MH(x) = -c^-\}$. Note that H is a concave function, which is easily checked by differentiation. Let $\bar{x} = \arg\max H(x)$, the point at which the maximum of H is achieved (it is easy to see that $H'(0) > 0$, whereas $\lim_{x\to\infty} H'(x) = -\infty$, which shows that $\bar{x}$ exists; in view of the fact that $H''(x) < 0$, it is unique). It is obvious by virtue of the concavity of H that, for any $M \le -c^-/H(\bar{x})$, $\tilde{b}_M$ and $\tilde{B}_M$ exist.

We now consider $I(M) = \int_{\tilde{B}^M}^{\bar{b}^M} (MH(x) + c^-)\,\mathrm{d}x$. Informally, $I(M)$ is the area under the graph of $MH(x)$ and above the horizontal line $y = -c^-$. It is obvious that $I(M)$ is a continuous function of M. For $M = -c^-/H(\bar{x})$, we have $\tilde{b}_M = \tilde{B}_M$; therefore $I(-c^-/H(\bar{x})) = 0$. We set $I(M)\to\infty$, as $M\to 0$, because $MH(x)\to 0$, whereas $\tilde{b}_M\to 0$ and $\tilde{B}_M\to\infty$. Therefore, there exists an M^* such that $I(M^*) = K^-$. We also have $\bar{b} = \tilde{b}_{M^*}$ and $\bar{B} = \tilde{B}_{M^*}$. Let

$$H^*(x) = \begin{cases} M^*H(x), & x \le \bar{b}, \\ -c^-, & x \ge \bar{b} \end{cases}.$$

Then,

$$v(x) = \int_0^x H^*(y)dy \tag{3.46}$$

is the optimal value function of the auxiliary problem (see Figure 2). The proof here is identical to that of a similar statement in Cadenillas *et al.* [7] and thus we omit it.

3.2 The Optimal Value Function for the Original Problem

We employ the function H^* obtained in the previous subsection to construct the derivative of the optimal value function V. The main idea is to consider $H^*(x+S)$ and try to find S such that $V'(x) = H^*(x+S)$. The optimal value function V will then be sought in the form of $v(x+S)$. To this end, we need the following proposition.

Proposition 3.1. *Suppose that $f(x)$ satisfies (3.39) (satisfies (3.40)); then, for any S, the function $f(x+S)$ satisfies the same equation on the interval shifted by S to the left.*

The proof of this proposition is straightforward.

From(3.45), we can see that H^* has a singularity at 0 with $\lim_{x\downarrow 0} H^* = -\infty$. The concavity of H^* on $[0, \bar{b}]$ implies that H^* is increasing on $(0, \bar{x}]$ and decreasing on $[\bar{x}, \infty)$ (recall that $H^*(x)$ is constant on $[\bar{b}, \infty)$). Therefore, there exists unique $0 < \bar{A} < \bar{B}$ such that $CH^*\left(\bar{A}\right) = -c^+$. Define

$$\overline{K^+} = \int_0^{\bar{A}} \left(-c^+ - CH^*(x)\right) \mathrm{d}x. \tag{3.47}$$

Note that H^* decreases to $-\infty$ at 0 at the order of $x^{\gamma-1}$ (see (3.45)); therefore, H^* is integrable at 0 and, as a result, $\overline{K^+} < \infty$.

The qualitative nature of the solution to the original problem depends on the relationship between K^+ and $\overline{K^+}$; hence, we divide our analysis into two cases.

3.2.1 The case of $K^+ \leq \overline{K^+}$.

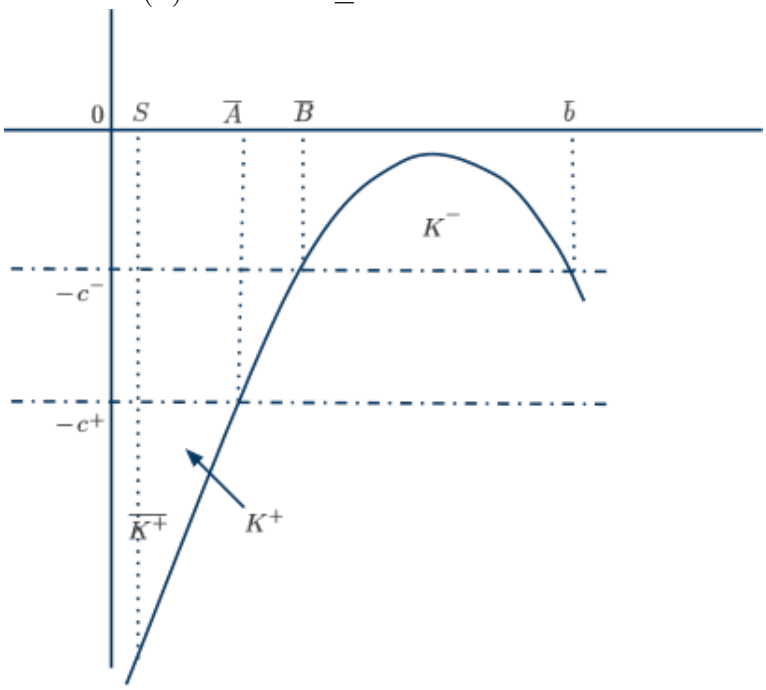

Consider the following integral

$$\mathcal{J}(S) = \int_S^{\bar{A}} -c^+ - H^*(y)dy$$

Geometrically this integral represents the area of a curvilinear triangle bounded by the lines $y = -c^+$, $x = S$ and the graph of the function $H^*(x)$. Obviously, $\mathcal{J}(S)$ is a continuous function of S. Because $\mathcal{J}(0) = \overline{K^+}$ and $\mathcal{J}(\bar{A}) = 0$, there exists an S^* (see Figure 3) such that

$$\mathcal{J}(S^*) = K^+. \tag{3.48}$$

Figure 3: Determining the parameters for the value function $V(x)$ by utilizing the solution of the auxiliary problem $H^*(x)$ when $K^+ \leq \overline{K^+}$.

In what follows, we show that $H^*(x + S^*)$ is the derivative of the solution V to the QVI, inequalities (2.12)-(2.14).

Let

$$V(x) = v(x + S^*). \tag{3.49}$$

Also let

$$A = \bar{A} - S^*, \tag{3.50}$$
$$b = \bar{b} - S^*, \tag{3.51}$$
$$B = \bar{B} - S^*, \tag{3.52}$$
$$x_0 = \tilde{x}_0 - S^*, \tag{3.53}$$
$$x^* = \bar{x} - S^*. \tag{3.54}$$

By virtue of Proposition 3.1, the function V satisfies (3.18) on $(0, x_0]$, as well as (3.23) on $[x_0, b)$. In addition, from (3.48), we can see that

$$V(0) - V(A) \equiv -\int_{S^*}^{\bar{A}} H^*(y)dy = c^+A + K^+. \tag{3.55}$$

From the construction of the function v, we can also see that

$$V(b) - V(B) \equiv v(\bar{b}) - v(\bar{B}) = -c^-(b - B) + K^-. \tag{3.56}$$

Theorem 3.1. *The Function V given by (3.56) is a solution to the QVI (2.12)-(2.14).*

The proof of this theorem is divided into several propositions.

Proposition 3.2. *The function V satisfies (3.16) on $[0, b)$.*

Proof. 1°. From the construction of the function v, we have $-\frac{\mu v'}{\sigma^2 v''} \leq 1$ on $(0, \tilde{x}_0]$. Consequently,

$$-\frac{\mu V'}{\sigma^2 V''} < 1 \tag{3.57}$$

on $(0, x_0]$. As V satisfies (3.18), it also satisfies (3.16) because these two equations are equivalent whenever (3.16) holds.

2°. To prove that (3.16) holds for $x \geq x_0$, it is sufficient to show that for each $0 \leq u \leq 1$,

$$\mathcal{L}^u V - rV \equiv \frac{1}{2}\sigma^2 u^2 V_2'' + \mu u V_2' - rV_2 = 0 \geq 0 \tag{3.58}$$

because, in view of Proposition 3.1, the function V satisfies (3.23) (that is, $\mathcal{L}^1 V - rV = 0$). By subtracting (3.58) from the left hand side of (3.23), we can see that (3.58) is equivalent to

$$\frac{1}{2}\sigma^2(1 - u^2)V_2''(x) + \mu(1 - u)V_2'(x) \leq 0 \tag{3.59}$$

for $x \in [x_0, b)$. In view of the continuity of the first and second derivatives, and in view of the fact that (3.16) holds on $(0, x_0]$, we know that (3.59) is true for $x = x_0$. As both $V' < 0$ and $V'' < 0$ on the left-hand side of (3.59) are decreasing, therefore is nonpositive for all $x \geq x_0$. □

Note that $\mathcal{M}\phi(x) = \min(\mathcal{M}_1\phi(x), \mathcal{M}_2\phi(x))$, where

$$\mathcal{M}_1\phi(x) = \inf_{\xi>0}[K^+ + c^+\xi + \phi(x+\xi)]; \;\; \mathcal{M}_2\phi(x) = \inf_{\xi>0}[K^- + c^-\xi + \phi(x-\xi)]$$

Proposition 3.3. *For each $x \geq 0$, we have*

$$\mathcal{M}V(x) \geq V(x). \tag{3.60}$$

If $x = 0$, or if $x \geq b$, then

$$\mathcal{M}V(x) = V(x). \tag{3.61}$$

Proof. 1°. We first prove, that $\mathcal{M}_1V(x) \geq V(x)$. Suppose that $x < A$. The functional $V(x+\xi) + c^+\xi$ is continuously differentiable. By construction, $V'(x) = H^*(x + S^*)$ is increasing on $(0, x^*)$ and decreasing on $[x^*, \infty)$ with $V'(x) \equiv -c^-$ for $x \geq b$. Therefore, the point A is the only point y such that $V'(y) \equiv H^*(y_S^*) = -c^+$. Because $(H^*)'(A) < 0$, we can see that $A = \arg\min_x V(x+\xi) + c^+\xi$. Therefore, for $x \leq A$,

$$\mathcal{M}_1V(x) = V(A) + c^+(A - x) + K^+.$$

Also, $\mathcal{M}_1V(x) - V(x) = V(A) - V(x) + c^+(A-x) + K^+ \geq 0$ iff

$$-c^+(A-x) - V(A) - V(x) \equiv \int_x^A [-c^+ - V(y)]dy \leq K^+.$$

However,

$$\int_x^A [-c^+ - V(y)]dy \leq \int_0^A [-c^+ - V(y)]dy \equiv \int_{S^*}^{\bar{A}} [-c^+ - H^*(z)]dz = K^+.$$

This proves that $M_1V(x) \geq V(x)$ for all $x \leq A$ and also shows that

$$\mathcal{M}_1V(0) = V(0). \tag{3.62}$$

Because $V'(y) > -c^+$ for $y > A$, we know that for any $x > A$ the function $V(x+\xi) + c^+\xi$ is an increasing function of $\xi > 0$. Therefore, the minimum in the expression for $\mathcal{M}_1$ is attained for $\xi = 0$; as a result, $\mathcal{M}_1(x) = V(x) + K^+ > V(x)$.

2°. Consider $V(x-\xi)-c^-\xi$ for $b>x\geq B$. Because $V'(y)>-c^-$ for $y>B$ and $V'(y)<c^-$ for $y<B$, we can see that $V(x-\xi)-c^-\xi$ has a unique minimum at $x-\xi=B$. Therefore, $\mathcal{M}_2V(x)=V(B)-c^-(x-B)+K^-$. Thus, $\mathcal{M}_2V(x)-V(x)\geq 0$ iff

$$V(x)-V(B)+c^-(x-B)\equiv\int_B^x V'(y)+c^-dy\leq K^-.$$

The foregoing inequality always holds true because, by construction,

$$K^-=\int_{\bar{B}}^{\bar{b}}H^*(y)+c^-dy\equiv\int_B^b V'(y)+c^-dy.$$

For $x\geq b$, we note, that $V(x)-V(b)=-c^-(x-b)$, and hence

$$\mathcal{M}_2V(x)-V(x)=\mathcal{M}_2V(b)-V(b)=V(B)-V(b)-c^-(b-B)+K^-=0. \tag{3.63}$$

□

To complete the proof of Theorem 3.1, we need only show the following.

Proposition 3.4. *If $x>b$, then (2.12) holds.*

Proof. It is sufficient to show that for any $0\leq u\leq 1$ and any $x>b$,

$$f(x)\equiv\frac{1}{2}u^2\sigma^2\frac{d^2V(x)\,(x)}{dx^2}+u\mu\frac{dV(x)\,(x)}{dx}-rV(x)\geq 0. \tag{3.64}$$

From Proposition 3.2 we know that (3.64) is true for $x=b-$. As $V''(b-)<0$, we obtain $(\mathcal{L}^uV)\,(b+)-rV(b+)=u\mu c^--rV(b)\geq 0$. For any $x>b$, we have $(\mathcal{L}^uV)\,(x)-rV(x)=u\mu c^--rV(x)>c^--V(b)$ because V is a decreasing function. □

This completes the proof of Theorem 3.1.

3.2.2 The case of $K^+>\overline{K^+}$

When $K^+>\overline{K^+}$ we cannot find any S^* such that (3.48) is satisfied. In this case, we set $V(x)=v(x)$ (that is, we have $S^*=0$, which corresponds to $A=0$).

Theorem 3.2. *If $K^+>\overline{K^+}$, then $V(x)=v(x)$ is a solution to the QVI (2.12)-(2.14).*

To prove this theorem, it is sufficient to prove Propositions 3.2-3.4. The proofs of Propositions 3.2 and 3.4 are identical to the case of $K^+ \leq \overline{K^+}$, whereas that of Proposition 3.3 requires a slight modification.

Proposition 3.5. *For each $x \geq 0$,*

$$\mathcal{M}V(x) \geq V(x). \tag{3.65}$$

If $x \geq b$, then

$$\mathcal{M}V(x) = V(x). \tag{3.66}$$

Proof. The proof that $\mathcal{M}_2 V(x) \geq V(x)$ for all x and that $\mathcal{M}_2 V(x) = V(x)$ for $x \geq b$ is the same as that in Proposition 3.3.

If $x \leq A$, then $\mathcal{M}_1 V(x) \geq V(x)$ is equivalent to

$$-c^+(A-x) - V(A) - V(x) \equiv \int_x^A [-c^+ - V(y)]dy \leq K^+.$$

The foregoing inequality is always true because

$$\int_x^A [-c^+ - V(y)]dy \leq \int_0^A [-c^+ - V(y)]dy = \overline{K^+} < K^+$$

by assumption.
If $x > A$, then $\mathcal{M}_1 V(x) \geq V(x)$ still holds, due to the same argument as that in Proposition 3.3. □

Remark 3.1. *In the case of $K^+ > \overline{K^+}$ we have $\mathcal{M}V(x) = V(x)$ only for $x \geq b$, whereas $\mathcal{M}V(0) > V(0)$ in contrast to the case when $K^+ \leq \overline{K^+}$. Also, when $K^+ > \overline{K^+}$, we have $V(0) = 0$, whereas $V(0) < 0$ if $K^+ \leq \overline{K^+}$. Equivalently, in the case that the fixed cost to call for additional funds is relatively large (i.e., $K^+ > \overline{K^+}$) , the optimal band control is reduced to $(0, 0; B, b)$ with $a = A = 0$. That is, as soon as the reserve reaches zero, it becomes optimal for the mutual insurance firm to go bankrupt, rather than to be restarted by calling for additional funds.*

4 Verification Theorem and the Optimal Control

Theorem 4.1. *If V is a solution to QVI (2.12)-(2.14), then for any control U,*

$$V(x) \leq C(x, U). \tag{4.67}$$

Proof. We prove this inequality when $K^+ \le \overline{K^+}$. In this case, $V'(0) = v'(S^*) > -\infty$. Let U be any admissible control defined by (2.2) and process $X(t)$ be the corresponding surplus process (2.3), with $X(0) = x$. Let τ be its ruin time given by (2.4). Let $\tau(t) = \tau \wedge t$ and $\tau_i(t) = \tau_i \wedge \tau \wedge t$. Then,

$$\begin{aligned} e^{-r\tau(t)}V(X(\tau(t))) - V(x) &= \sum_{i=1}^{\infty}\left[e^{-r\tau_i(t)}V\left(X\left(\tau_i(t)-\right)\right) - e^{-r\tau_{i-1}}(t)V\left(X\left(\tau_{i-1}(t)\right)\right)\right] \\ &\quad + \sum_{i=1}^{\infty} e^{-r\tau_i(t)}\left[V\left(X\left(\left(\tau_i(t)\right)\right)\right) - V\left(X\left(\tau_i(t)-\right)\right)\right]. \end{aligned} \tag{4.68}$$

By convention, $\tau_0 = 0$. In view of (2.13), we have $|V(x)-V(y)|(c^+|y-x|+K^+)\mathbb{1}_{y<x} + (K^- - c^-|y-x|)\mathbb{1}_{y>x}$. Therefore, $|V(X(\tau_i(t))) - V(X(\tau_i(t)-))|(c^+\xi_i^+ + K^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i^-)\mathbb{1}_{\xi<0}$ and

$$\begin{aligned} \left|\sum_{i=1}^{\infty} e^{-r\tau_i(t)}\left[V\left(X\left(\tau_i(t)\right)\right) - V\left(X\left(\tau_i(t)-\right)\right)\right]\right| &\le \sum_{i=1}^{\infty} e^{-r\tau_i(t)}\left|V\left(X\left(\tau_i(t)\right)\right) - V\left(X\left(\tau_i(t)-\right)\right)\right| \\ &\le \sum_{i=1}^{\infty} e^{-r\tau_i(t)}\left[(c^+\xi_i^+ + K^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i^-)\mathbb{1}_{\xi_i<0}\right] \\ &\le \sum_{\tau_i\le\tau} e^{-r\tau_i}\left[(c^+\xi_i^+ + K^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i^-)\mathbb{1}_{\xi_i<0}\right] \end{aligned} \tag{4.69}$$

In view of (2.6), this implies that for any t the second sum in (4.68) is bounded by the same integrable random variable independent of t.

On $[\tau_{i-1}, \tau_i]$, process $X(t)$ is continuous, and we can apply Ito's formula to get

$$\begin{aligned} e^{-r\tau_i(t)}V\left(X\left(\tau_i(t)-\right)\right) - e^{-r\tau_{i-1}}(t)V\left(X\left(\tau_{i-1}(t)\right)\right) &= \int_{\tau_{i-1}(t)}^{\tau_i(t)} e^{-rs}\left[\mathcal{L}^{u(s)}V\left(X(s)\right) - rV\left(X(s)\right)\right]ds \\ &\quad + \int_{\tau_{i-1}(t)}^{\tau_i(t)} e^{-rs}V'\left(X(s)\right)u(s)\sigma dW(s). \end{aligned} \tag{4.70}$$

From this equation, using (2.6) and standard but rather tedious arguments, we can deduce that the first sum in (4.69) for all t is also bounded by the same integrable random variable. Similar arguments show that

$$\lim_{t\to\infty} E[e^{-r\tau(t)}V(X(\tau(t)))\mathbb{1}_{\tau=\infty}] = 0 \tag{4.71}$$

and

$$\lim_{t\to\infty} E[e^{-r\tau(t)}V(X(\tau(t)))] = E[e^{-r\tau}V(X(\tau))\mathbb{1}_{\tau<\infty}]. \tag{4.72}$$

(see Cadenillas *et al.* [7]). Note that the second integral on the right-hand side of (4.70) is a martingale whose expectation vanishes. However, in view of (2.12), the integrand in the first integral of (4.70) is nonnegative. Therefore,

$$E[e^{-r\tau_i(t)}V(X(\tau_i(t)-)) - e^{-r\tau_{i-1}}(t)V(X(\tau_{i-1}(t)))] > 0, \tag{4.73}$$

and, taking into account the dominated convergence theorem, we can see that the expectation of the first sum on the right-hand side of (4.68) is nonnegative.

From (2.13), we can see that $V(X(\tau_i)) - V(X(\tau_i-)) \equiv V(X(\tau_i-)+\xi_i) - V(X(\tau_i-)) \geq -[(K^+ + c^+\xi_i)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i)\mathbb{1}_{\xi_i<0}]$. Substituting this inequality into (4.68) and taking expectations of both sides, we obtain

$$E[e^{-r\tau(t)}V(X(\tau(t)))] - V(x) \geq -E\sum_{\tau_i\leq\tau,\tau_i\leq t} e^{-r\tau_i}[(K^+ + c^+\xi_i^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i^-)\mathbb{1}_{\xi_i<0}] \tag{4.74}$$

Letting $t\to\infty$, and employing (4.72) and the monotone convergence theorem on, we get

$$E[e^{-r\tau}V(X(\tau))1_{\tau<\infty}] - V(x) \geq -E\sum_{\tau_i\leq\tau} e^{-r\tau_i}[(K^+ + c^+\xi_i^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi_i^-)\mathbb{1}_{\xi_i<0}] = -C(x,U) \tag{4.75}$$

As $V(X(\tau)) \leq 0$, on $\{\tau < \infty\}$, the inequality (4.75) implies (4.67) □

Remark 4.1. *For the expectation of the stochastic integral on the right hand side of (4.70) to vanish, it is sufficient for its integrand to be bounded. In particular, it is sufficient for V' to be bounded. This is the case when $K^+ < \overline{K^+}$. When $K^+ \geq \overline{K^+}$, the function V' has a singularity at 0. We can, however, apply the same technique, first replacing τ by $\tau^\epsilon = \inf\{t : X(t) < \epsilon\}$ and then passing to a limit as $\epsilon\to 0$. This will yield inequality (4.74), which is all we need for the proof of Theorem 4.1*

Let $\mathcal{H}^*(x) = \arg\min_u\{\mathcal{L}^u V(x) - rV(x)\}$, that is

$$\mathcal{L}^{\mathcal{H}^*(x)}V(x) - rV(x) = 0 \tag{4.76}$$

From (3.46),(3.45), (3.49), and (3.53), we can see that

$$\mathcal{H}^*(x) = \min\{x/(x_0 + S^*), 1\}.$$

Consider the process defined as

$$X^*(t) = X(\tau_{\tau_i}) + \int_{\tau_i}^{t} \mu\mathcal{H}^*(X^*(s))ds + \int_{\tau_i}^{t} \sigma\mathcal{H}^*(X^*(s))dW_s \tag{4.77}$$

$i = 0, 1, ...,$ with $\tau_0 \equiv 0$, $X(\tau_0) \equiv X(0) = x$, and τ_i and $X(\tau_i)$ are defined below sequentially.

If $\overline{K^+} < K^+$(that is, no S^* exists, such that (3.48) holds), then

$$\tau_i = \inf\{t : X^*(t) \geq b\} \tag{4.78}$$

$$X^*(\tau_i) = B, \;\; \xi_i = b - B. \tag{4.79}$$

If $\overline{K^+} \geq K^*$ (that is, there exists an S^*, such that (3.48) holds), then

$$\tau_i = \inf\{t : X^*(t) \notin [0, b]\} \tag{4.80}$$

$$X^*(\tau_i) = \begin{cases} B, \;\; \xi_i = b - B & X^*(\tau_i-) = b, \\ A, \;\; \xi_i = A & X^*(\tau_i-) = 0. \end{cases} \tag{4.81}$$

Remark 4.2. *Informally, if $\overline{K^+} < K^+$, then process $X^*(s)$ is a continuous diffusion process with a drift and diffusion coefficient of, $\mu\mathcal{H}^*(X^*(s))$ and $\sigma\mathcal{H}^*(X^*(s))$, respectively, until the times of intervention. The times of intervention in this case are the times at which this diffusion process hits the level b, which are associated with the refunds of the constant amount of $b - B$. The time when 0 is hit is the ruin time.*

When $\overline{K^+} \geq K^+$, the process $X^*(s)$ is a continuous diffusion process with the same drift and diffusion coefficients as above, between the times of intervention. The intervention times are the times at which this process reaches either 0 or b. At point 0, the control is set to displace the process to point A, which corresponds to raising cash (making a call to shareholders) in the amount of A. Reaching the level b results in the displacement of the process to the point B which, corresponds to making a refund in the amount of $b - B$.

Theorem 4.2. ***(The verification theorem)*** *Let U^* be the control described by (4.76) and (4.78)-(4.81). Then,*

$$C(x, U^*) = V(x) = \inf_{U \in \mathcal{U}} C(x, U)$$

Proof. In view of (4.67), it is sufficient to show that

$$C(x, U^*) = V(x). \tag{4.82}$$

Equality (4.76) shows that

$$\mathcal{L}^{\mathcal{H}^*(X^*(s))}V(X^*(s)) - rV(X^*(s)) = 0. \tag{4.83}$$

From Propositions 3.3 and 3.5, we know that $V(b)-V(B) = K^- - c^-(b-B)$ and if $\overline{K^+} \geq K^+$ then $V(0) - V(A) = K^+ + c^+A$. Thus, we can repeat the arguments in the proof of Theorem 3.2 and see that, for $U = U^*$, all of the inequalities are tight. As a result, we obtain

$$E[e^{-r\tau}V(X(\tau))\mathbb{1}_{\tau<\infty}] - V(x) = -E\sum_{\tau_i \leq \tau} e^{-r\tau_i}[(K^+ + c^+\xi^+)\mathbb{1}_{\xi_i>0} + (K^- - c^-\xi^-)\mathbb{1}_{\xi_i<0}] = C(x, U^*). \tag{4.84}$$

Because we know that, when $\overline{K^+} \geq K^+$, we have $\mathbb{1}_{\tau<\infty} = 0$ and, when $\overline{K^+} < K^+$, the function V satisfies $V(0) \equiv v(0) = 0$, the first term on the left-hand side of (4.84) vanishes, and we get (4.82). □

5 Conclusions

The optimal policy in this model has several interesting nontrivial features. The fact that calls should be made only when there is no possibility of waiting any longer (that is when the reserve reaches zero) is supported by intuition. However, the qualitative structure of the optimal policy and its dependence on the model parameters are not as obvious.

It turns out that it is always optimal to pay dividends, no matter what the costs associated with such payments are. However, raising cash may not be optimal when the initial set-up cost is too high. Quantity $\overline{K^+}$, which determines the threshold for set-up cost K^+, such that if the cost is higher than this threshold then it is optimal to allow ruin, is in itself determined via an auxiliary problem with a one-sided impulse control. Although there is no closed-form expression for the quantity $\overline{K^+}$, it can be determined in an algorithmic manner prior to solving the optimal control problem for the mutual insurance company.

There is one rather curious feature of the optimal solution when $K^+ = \overline{K^+}$. As our analysis shows, in this case, $S^* = 0$ and $V = v$, the same as is the case when $K^+ > \overline{K^+}$. However, from the construction of the optimal policy, we can see that the two band-type policy is optimal in this case as well. In this borderline case, we thus have two optimal

policies, one for which $\tau = \infty$ with the lower band equal to $(0, A)$ and one for which reaching 0 corresponds to ruin and for which $\tau < \infty$. This is a rather unique feature of this particular problem that has not been observed previously.

A natural question arises: what if ruin is explicitly disallowed, and we must find an optimal policy from among those for which $\tau = \infty$. As can be seen from our analysis, we find a solution to this problem for the case of $\overline{K^+} \geq K^+$. However, when this inequality does not hold, then of the stochastic control technique and the HJB equation used in this paper do not work. Another approach should be developed, as can be seen indirectly in the work of Eisenberg [12] and Eisenberg and Schmidli [13], where a similar (although not identical) problem is considered for the case of a surplus process modeled via the classical Cramer-Lundberg model. This constitutes an interesting and challenging problem for future study, the nature of whose solution is not obvious at this time.
